ABSTRACT

We identify 709 arc-shaped mid-infrared nebula in 24 μm *Spitzer Space Telescope* or 22 μm *Wide Field Infrared Explorer* surveys of the Galactic Plane as probable dusty interstellar bowshocks powered by early-type stars. About 20% are visible at 8 μm or shorter mid-infrared wavelengths as well. The vast majority (660) have no previous identification in the literature. These extended infrared sources are strongly concentrated near Galactic mid-Plane with an angular scale height of ∼0.6°. All host a symmetrically placed star implicated as the source of a stellar wind sweeping up interstellar material. These are candidate "runaway" stars potentially having high velocities in the reference frame of the local medium. Among the 286 objects with measured proper motions, we find an unambiguous excess having velocity vectors aligned with the infrared morphology — kinematic evidence that many of these are "runaway" stars with large peculiar motions responsible for the bowshock signature. We discuss a population of "in-situ" bowshocks (∼103 objects) that face giant H II regions where the relative motions between the star and ISM may be caused by bulk outflows from an overpressured bubble. We also identify ∼58 objects that face 8 μm bright-rimmed clouds and apparently constitute a sub-class of in-situ bowshocks where the stellar wind interacts with a photo-evaporative flow from an eroding molecular cloud interface (i.e., "PEF bowshocks"). Orientations of the arcuate nebulae exhibit a correlation over small angular scales, indicating that external influences such as H II regions are responsible for producing some bowshock nebulae. However, the vast majority of this sample appear to be isolated (499 objects) from obvious external influences.

Keywords: Stars: massive — Interstellar medium (ISM), nebulae — surveys (ISM:) HII regions (Stars:) early-type — Stars: kinematics and dynamics —

1. INTRODUCTION

Stellar bowshock nebulae are arcuate structures created by the interaction between stellar winds and the surrounding interstellar medium (ISM) where the relative velocity between the two is supersonic (van Buren et al. 1990; Mac Low et al. 1990). A shock front forms at the interface of the high speed stellar wind and the ambient interstellar medium. The swept up interstellar dust and gas ahead of the high-velocity star forms an arc-like feature preceding the peculiar motion of the star. This material is most clearly visible in the mid-infrared and sometimes in optical emission lines such as Hα and O III (Brown et al. 2005; Meyer et al. 2014, 2016). Most bowshock nebulae are observed around high-velocity massive stars, but they have also been identified preceding high-velocity pulsars (Wang et al. 2013), red supergiants (Noriega-Crespo et al. 1997), and associated with proplyds in the Orion Nebula (Bally et al. 1998). Wilkin (1996) derived an exact analytic solution for this interaction by balancing the ISM pressure and ram pressure of the stellar winds. Based on this model, Comerón & Kaper (1998); Meyer et al. (2014, 2016) used computer simulations to demonstrate that stable bowshocks can be formed for a variety of interaction scenarios over a range of relative velocities, ISM densities, and stellar wind momentum fluxes.

A significant proportion (10±25%) of early-type stars reside outside of stellar clusters Gies & Bolton (1986). Because of their short main-sequence lifetimes these stars, known as runaway stars, must be moving at high peculiar velocities,

typically >30 km s^{-1} (Gies & Bolton 1986). Stone (1991) found that O and B type stars (OB stars) comprise 50% of all runaway stars, and these OB runaways are dominated by O type stars (12:1). Two general scenarios that generate runaway stars have been proposed: close dynamical interactions of either single stars (Poveda et al. 1967) or binary-binary interactions (Spitzer & Mathieu 1980), and ejection from close binary systems when the more evolved member undergoes a core-collapse supernova (CCSN; Zwicky 1957; Blaauw 1961).

Poveda et al. (1967) analytically simulated the dynamical interactions of small clusters of 5–6 50 M$_\odot$ stars and found that 2–17% of these stars were ejected from the cluster with velocities in excess of 35 km s^{-1}. Kroupa et al. (2001) concluded that dynamical few-body ejections of OB stars likely occur in the first $\lesssim 1$ Myr of the cluster's history before the radiation of the OB stars expels the mass-dominant gas component of the cluster, causing the cluster to expand. Leonard (1991) simulated binary-binary gravitational interactions and found a maximum ejection velocity of 700 km s^{-1} for 60 M$_\odot$ stars and 1400 km s^{-1} for 1–4 M$_\odot$ stars. Though the initial multiplicity fraction of OB stars is unknown, studies have shown that the fraction is likely higher than 60% in stellar clusters, meaning that at least 75–90% of massive stars are in a multiple system and have the potential to participate in few-body interactions (García & Mermilliod 2001; Sana et al. 2012; Kiminki & Kobulnicky 2012; Kobulnicky et al. 2014).

Zwicky (1957) first proposed that stars that form in close binary systems could be ejected when one of the components explodes as a supernova. Liu et al. (2015) hydrodynamically simulated the effects of asymmetric CCSN in close binary systems and determined that the less-evolved companion could survive with minimal disruption and be ejected at runaway velocities. Fryer et al. (1998) used Monte Carlo simulations to determine the necessary impulse to account for the observed velocity distribution of pulsars and found by extension that the necessary forces could accelerate the surviving OB companions to velocities up to 100 km s^{-1}. Tauris (2015) expanded upon this work with new simulations and found that early-type B stars (10 M$_\odot$) could be accelerated up to $\sim$320 km s^{-1} under ideal conditions with increasing maximum velocities for lower mass stars (up to $\sim$1050 km s^{-1} for a 0.90 M$_\odot$ star).

It is likely that both few-body interactions and supernovae in binary systems combine to generate the observed population of runaway stars. Using Hipparcos proper motions Hoogerwerf et al. (2000) traced the motions of two known runaway stars, AE Aur and μ Col (O9.5V and O9.5B/B0, moving in opposite directions at 100 km s^{-1}) to a common origin $\sim$2.5 million years ago near the location of the binary pair ι Ori. They proposed that the two runaways may have been ejected in a binary-binary interaction. Gvaramadze et al. (2013) identified two O-type runaways that may have been ejected from the star cluster NGC 3603 in a single star-binary interaction when the single star captured one binary member and ejected the other with both systems being accelerated to high peculiar velocities relative to the cluster. The new binary system later merged into the single 'blue straggler' star observed. Hoogerwerf et al. (2000) used Hipparcos proper motions to trace ζ Oph and the pulsar J1932+1059 back to the same region of the Upper Scorpius star forming region $\sim$1 Myr ago, which could indicate that the two were once members of a common binary prior to the supernova creating the pulsar. Hoogerwerf et al. (2001) identified eight additional binary-binary and 16 binary-supernova ejection candidates by extrapolating their proper motions. A fraction of the ejected stars in the Liu et al. (2015) simulations accreted material from the CCSN, and these simulations predict that atmospheric chemical enrichments may be observable in the runaway stars if mixing is inefficient. Several runaway stars (Blaauw 1993; Gvaramadze 2009) have been observed with significant α-element enrichment, consistent with this prediction.

Hybrids of these ejection scenarios may also be possible. Pflamm-Altenburg & Kroupa (2010) suggested that a two-step scenario involving a dynamically ejected binary pair could accelerate a single runaway star following a CCSN. Because of the two kicks accelerating the star in this scenario, the star's observed proper motion vector may not point back to a cluster. de Wit et al. (2005) examined a sample of known runaway stars and found that 4±2% do not have proper motions that can be extrapolated back to a known cluster or association.

Hypervelocity stars (HVSs) are a special class of runaway stars with extremely high space velocities, typically defined as being greater than 400 km s^{-1} (Kenyon et al. 2008). Hills (1988, 1991) first predicted hypervelocity stars when modelling the close interaction of binary star systems with a supermassive black hole (SMBH), which produced stars with velocities in excess of 1000 km s^{-1}. Yu & Tremaine (2003) proposed two additional mechanisms: gravitational interaction between a pair of single stars with a extreme mass ratio or stellar acceleration by a binary SMBH system. However, they predicted that the HVS generation rate by single star interactions is likely low enough to be undetectable due to the extremely small impact parameter required. Brown et al. (2005) reported the discovery of the first HVS in the Galactic Halo, SDSS J090745.0+024507, a main sequence B star (Fuentes et al. 2006) which remains the fastest observed HVS with a Heliocentric radial velocity of 831.1±5.7 km s^{-1} (Brown et al. 2014). Brown et al. (2014) assembled the most complete catalog of HVSs with 24 confirmed objects and several additional candidates. Several simulations (Brown et al. 2005; Meyer et al. 2014, 2016) have demonstrated that it is unlikely that HVSs can support visible bowshock nebulae due to their high velocities inhibiting the accumulation of material in the leading shock.

Two general classes of bowshock nebulae are generally recognized: those supported by runaway stars, and "in-situ" bowshocks supported by a star overrun by an outflow of hot gas from a star-forming or H II region. Gull & Sofia (1979) used optical emission line imaging to catalog the first bowshock nebulae which appeared as "distorted interstellar bubbles". These nebulae were observed around the prototypical runaway ζ Oph and around the star LL Ori situated in an outflow from θ^1 Ori in the Orion Nebula. Povich et al. (2008) cataloged six arcuate nebulae around the star-forming regions M 17 and RCW 49 and identified these in-situ shocks as a distinct class. The associated physics of these in-situ shocks are similar to runaway bowshocks when considered within the rest frame of the stellar source.

Using 60 μm images from the Infrared Astronomical Satellite ($IRAS$) (Neugebauer et al. 1984) van Buren & McCray (1988) compiled the first catalog of bowshock nebulae. A more complete sample gathered from $IRAS$ images found a total of 58 bowshock nebula candidates around 188 runaway OB stars (van Buren et al. 1995). Subsequent re-analysis of $IRAS$ all-sky images concluded only 19 of the 58 candidate were bowshock nebulae with 2 additional questionable candidates (Noriega-Crespo et al. 1997). The increased angular resolution of infrared surveys conducted by the Spitzer Space Telescope (SST) and Wide-Field Infrared Survey Explorer ($WISE$) (Wright et al. 2010), enabled the identification of small collections of bowshock nebulae in both the LMC (Gvaramadze et al. 2010) and SMC (Gvaramadze et al. 2011a), generated by stars ejected from the star-forming regions NGC 6611 (Gvaramadze & Bomans 2008), Cygnus OB2 (Kobulnicky et al. 2010), NGC 6357 (Gvaramadze et al. 2011c), NGC 3603 (Gvaramadze et al. 2013), and Carina Nebula (Sexton et al. 2015), and powered by high-mass X-ray binaries (Gvaramadze et al. 2011b), pulsars (Wang et al. 2013), red (Noriega-Crespo et al. 1997; Cox et al. 2012; Gvaramadze et al. 2014a) and blue (Gvaramadze et al. 2014b) supergiants, and the A-type star δ Vel (Gáspár et al. 2008). Peri et al. (2012, 2015) conducted the most extensive search to date for bowshock nebulae and runaway stars by examining $WISE$ archival images in the vicinity of several hundred runaway star candidates identified by Tetzlaff et al. (2010). The most recent release of their E-BOSS (Extensive Bow Shock Survey) catalog (Peri et al. 2015) contains a compilation of 73 bowshock nebulae candidates found in their visual search and those previously identified in the literature. Based on their work, it appears that 5–10% of runaway stars support bowshock nebulae, though some earlier studies have suggested higher rates of ~15% (van Buren et al. 1995) or as high as ~30% (van Buren & McCray 1988).

The present paper is the first in a series presenting and analyzing a new catalog of candidate bowshock nebulae. Our group has taken the opposite approach of the E-BOSS survey (Peri et al. 2012, 2015) by conducting a comprehensive visual inspection of existing space-based infrared surveys to identify candidate bowshock nebulae and runaway stars along the Galactic mid-Plane. In this paper, we report the identification of 708 candidate bowshock nebulae, 659 of which have not been previously identified in the literature. This catalog constitutes the largest collection of bowshock nebula candidates by an order of magnitude. In Chick et al. (2016), we present the results of spectroscopic follow-up of nearly 100 targets, that >95% of these infrared-selected stellar sources are, in fact, early-type massive stars, and that infrared nebular morphology alone is enough to select massive stars with confidence. In Section 2, we discuss the selection process and space-based infrared datasets used for identifying candidate nebulae. Section 3 presents the archival infrared images of our candidates and discusses the demographics of our sample including the sky distribution, proper motions, and their surrounding environments. We summarize our results in Section 4.

2. BOWSHOCK CANDIDATE IDENTIFICATION

2.1. *Infrared Survey Data and Strategy Employed*

Our team conducted a visual examination of mid-infrared images from *Spitzer Space Telescope* (SST; Werner et al. 2004) and the Wide-field Infrared Survey Explorer (WISE; Wright et al. 2010) to locate bowshock nebula candidates. The *Spitzer Space Telescope* data included several wide-area surveys conducted using the Infrared Array Camera (IRAC; Fazio et al. 2004) in its 3.6, 4.5, 5.8, and 8.0 μm bandpasses along with 24 μm data from the Multiband Imaging Photometer for Spitzer (MIPS; Rieke et al. 2004). The *Spitzer Space Telescope* beam size at these bands is 1.66, 1.72, 1.88, 1.98 and 6″ FWHM, respectively[1]. Survey data included images obtained as part of the Galactic Legacy MidPlane Survey Extraordinaire I and II (GLIMPSE, GLIMPSE II; Benjamin et al. 2003) and MIPSGAL (Carey et al. 2009) programs, the the *Spitzer* Legacy Survey of the Cygnus-X Complex (Hora et al. 2007), and the *Spitzer* Mapping of the Outer Galaxy (SMOG; Carey et al. 2008). Together these SST surveys cover slightly more than 304 square degrees of the Galactic Plane — a large continuous strip at $-65° < \ell < 65°$, $|b| \lesssim 1°$ (GLIMPSE and MIPSGAL), a 24 square degree regions near $\ell = 79°$ (Cyg-X), and a $2° \times 10°$ strip centered on $\ell = 105°$ (SMOG). Our search used the large mosaics at each waveband constructed by the GLIMPSE team that are available at the Spitzer

http://irsa.ipac.caltech.edu/data/SPITZER/docs/mips/mipsinstrumenthandbook

Science Center. The $WISE$ data include images at the 3.4, 4.6, 12, and 22 μm bandpasses which have beamsizes of 6.1″, 6.4″, 6.5″, and 12.0″ FWHM, respectively. Our search of the $WISE$ all-sky survey images (about 460 square degrees of the Outer Galaxy) used 1° mosaics in regions along the Galactic Plane not covered by Spitzer and the Centre de Données astronomiques de Strasbourg's Aladin[2] interface which allows a viewer to rapidly browse large regions of the sky. Given the concentration of bowshock nebulae very near the Galactic Plane (Section 3.2), our search of the $WISE$ data concentrated on regions $|b| < 2°$, but we also performed a cursory search using the Aladin (Bonnarel et al. 2000) Lite interface up to $|b| < 10°$. Only a few objects were discovered beyond $b = \pm 1°$.

We searched the SST mosaics for 1) arc-shaped or lima-bean-shaped nebulae at 24 μm and/or 8.0 μm that had 2) a high degree of symmetry with 3) at least one prominent star located near the axis of symmetry visible at 4.5 μm. For the majority of candidates, there is a single bright star located along the axis of symmetry; it constitutes the obvious early-type stellar candidate, even though there is no spectral information available for the vast majority of candidates. In some cases there are multiple candidate stars within the arc, and in a few cases there are no prominent stellar candidates, especially in the inner Galaxy where the stellar density is high and even early type stars may appear faint because they are located at large distances.

Our initial visual search team interpreted these three criteria liberally. The Galactic Plane exhibits very complex structures at 8.0 and 24 μm that vary greatly in surface brightness over small angular scales, producing a large number of initial candidates that do not meet one of more of the three search criteria. The final decision regarding which objects met all three criteria was ultimately made by the senior author (HAK). Relaxing these criteria would substantially increase the candidate list by at least a factor of two. The search process involved examining color representations of the 4.5, 8.0, and 24 μm images displayed with a square-root color stretch. Owing to the high dynamic range of the mosaics, it was necessary to use a variable maximum and minimum intensity levels to achieve the needed contrast, depending on the surface brightness in each region. Often in regions of large dynamic range several different scalings were used. This was necessary to find nebulae superimposed on regions with high background levels (e.g., within H II regions). No quantitative thresholds were used in the search process; indeed, the rms noise levels are not well defined, varying significantly on small spatial scales where regions of very high and very low surface brightness appear adjacent to one another. The maximum angular size of a detectable candidate is limited by the size of the survey mosaics at about 2 degrees; in practice, there are no candidates larger than 8.6′. The angular resolution of the $SST/WISE$ surveys, described above, sets the lower limit on the angular size of detectable candidates.

Two or more team members searched each region of the Plane. In comparing candidate lists identified by each searcher we concluded that there was at least a 50–75% overlap between the candidate lists. Each searcher identified candidates not found by the others. We estimate that use of additional searchers could increase the current candidate list, most of this gain coming in areas of the Plane dominated by high-surface brightness H II regions. A search such as this can never be deemed "complete" given the inherent subjectivity of what constitutes "arc-shaped" or "symmetric", especially in regions having large changes in surface brightness over small angular scales where genuine bowshock nebulae may be confused with unrelated foreground or background emission.

All SST objects were discovered initially in the 24 μm bandpasses where emission is either thermal in nature or from (semi-)stochastic heating of small dust grains. Only a minority of the bowshock candidates exhibit morphologically similar counterparts in the 8.0 μm band, which predominantly includes a broad solid-state emission feature from polycyclic aromatic hydrocarbons (PAHs). However, the 8.0 μm band may also include a contribution from very hot dust near the sublimation temperature.

Our search of the WISE images concentrated on the 22 μm (W4) band for nebula identification and the 4.6 μm (W2) band for identification of a stellar source. We find that nearly all candidates identified in the W4 band also had counterparts in the 12 μm (W3) band, which may include both PAH and hot dust emission. Owing to the superior angular resolution of SST compared to WISE – 6.0″ at 24 μm versus 12.0″ FWHM at 22 μm – we gave preference to the SST data (where available) and did not search the overlapping $WISE$ images.

Because the $WISE$ beamsize is twice that of the SST at the longest wavelengths, objects that would appear arcuate in SST imaging might appear circular in $WISE$ and, therefore, be rejected from the catalog. This leads to a kind of systematic decrease in the completeness (at fixed angular sizes of 6–12″) for the regions surveyed only with $WISE$. Similarly, we find a large number of small circular 24 μm nebulae near the angular resolution limit of SST that might appear arcuate if viewed under higher angular resolution.

Additionally, bowshock candidates listed in the literature were examined and retained if they met our mor-

phological selection criteria described above. Our survey of the literature included the compilations of Peri et al. (2015, Pe15), Sexton et al. (2015, S15), Peri et al. (2012, Pe12), Gvaramadze et al. (2011c, G11), Kobulnicky et al. (2010, K10), Gvaramadze & Bomans (2008, G08), Povich et al. (2008, P08), Comerón & Pasquali (2007, CP07), Noriega-Crespo et al. (1997, N97), and van Buren & McCray (1988). The final collection tabulated here does not include many of the candidates listed in these works, primarily because they fail to meet one of more of the morphological criteria.

2.2. *Search Results*

Table 1 lists parameters for the probable central stars of the 709 candidate bowshock nebula. The first twenty rows appear in the printed Journal to give guidance as to the table format and content. The entire table is available in digital format in the electronic edition. Column 1 is a sequential identification number unique to this work, column 2 is a generic name in Galactic coordinates, while columns 3 and 4 list the J2000 right ascension and declination for the putative central star. Column 5 gives the publication where the candidate is first identified as a bowshock candidate. A "T" indicates "this work", and other abbreviations refer to published works, as referenced fully in the table footnotes. Of the 709 tabulated objects, 660 are identified herein as bowshock candidates for the first time. Column 6 lists another common alias for the central stellar source, if one exists in the literature, such as an HD (Henry Draper Catalog) designation. Fully 581 of the 709 stellar sources have no alternate designation in the literature, indicating that the vast majority of the objects are faint and highly reddened. Column 7 is a single character designating whether the nebular object has an SST IRAC 8.0 counterpart with a similar morphology (Y), has no detection above background levels at this waveband (N), or has no data from IRAC (-).[3] We find that 130 of the 626 objects having IRAC data show a nebula at 8.0 μm, indicating a probable PAH contribution. Column 8 contains a single alphanumeric code, "C", in cases where the probable central stellar source is uncertain owing to faintness or to the presence of multiple stars of similar magnitude near the nebular axis; 115 objects fall into this category. In such cases we adopt the brightest point source nearest the axis of symmetry as the most probable star, but we urge caution with regard to the certainty of this identification. Columns 9 and 10 list the distance R_0 (in arcsec) from the putative central star to the apsis of the candidate bowshock and the position angle (in degrees from N toward E) of this vector in equatorial coordinates. These values were measured by eye and carry typical uncertainties of $1\rlap{.}''5$ and $5°$, respectively. Columns 11 and 12 list the 2MASS H-band and IRAC 4.5/WISE 4.6 μm magnitudes of the central star, obtained from the 2MASS (Skrutskie et al. 2006) and GLIMPSE/WISE catalogs, respectively. In just a handful of cases (19), no H-band source is measured, implying an extremely red, highly extinguished object. Column 13 lists an estimate of the K-band extinction to each source, inferred using the H−4.5 color and the Rayleigh-Jean Color Excess formulation of Majewski et al. (2011).

The final column of Table 1 provides additional descriptors that characterize the local environment of each stellar candidate. Column 14 contains an alphanumeric code that describes the immediate environment of each candidate as either isolated (I; 499 instances), directly facing a large H II region within about 10 arcminutes (FH; 103 instances), facing a bright-rimmed cloud prominent at 8.0 μm within several arcminutes (FB; 58 instances), or situated within a giant H II region (H; 49 instances). In some cases two designations could apply, for example, a candidate that lies within an H II region that also faces a bright-rimmed cloud. In such cases FB is given preference over H. Objects designated FH may be instances of the "in-situ" bowshocks (Povich et al. 2008). These descriptors are qualitative judgments of the candidates' immediate environments intended to elucidate possible physical origins for what we regard as potentially different classes of bowshock nebulae. Given the unknown distances of each object and complex sightlines in the Galactic Plane, physical connections between bowshock candidates and other objects nearby on the sky are necessarily uncertain. Section 3.5 will discuss example objects in each of these five categories in more detail.

3. PROPERTIES OF THE BOWSHOCK CANDIDATES

3.1. *Infrared Images*

Figure 1 shows a collage of three-color representations for six objects from Table 1 that may be regarded as prototypical bowshock nebulae. The angular scale of each panel differs to accommodate the size of each object. Each panel displays a highly resolved, unmistakable arc-shaped nebulae and a bright central star with a substantial proper motion consistent with the nebular bowshock orientation. These six objects are ζ Oph (G006.2812+23.5877; upper left), AE Aur (G172.0813−02.2592; upper right), HD136003 (G322.6802+00.9060; center left), HD150898 (G329.9790−08.4736;

---

[3] Essentially all of the objects detected in the WISE 22 μm band also have counterparts in the WISE 12 μm band. Therefore, we do not tabulate detections for the WISE bandpasses.

center right), HD155755 (G348.7967+00.1455; lower left), HD143275 (G350.0969+22.4904; lower right), as "proto-typical" examples of bowshock nebulae drawn from the literature. We use a color scale that depicts the SST 24 μm or $WISE$ 22 μm image in red, the SST 8.0 or $WISE$ 12 μm image in green, and the SST 3.6 or $WISE$ 3.6 μm image in blue. A white arrow depicts the proper motion vector magnitude and direction. Images of G322.6802+00.9060 and G348.7967+00.1455 use IRAC data so the nebula is dominated by 24 μm emission (red) and appears red, while the other four use $WISE$ data, and the combination of 22 μm (red) and 12 μm (green) emission results in a yellowish appearance.

Figure 1 reveals that only a minority of the objects display the ideal ("theoretical") bowshock morphology — e.g., see Figure 1 of Wilkin (1996) or Figure 9 of Meyer et al. (2016) or Figure 3 of Acreman et al. (2016) for a variety of viewing inclination angles). The ζ Oph nebula (upper left) appears flocculent and significantly asymmetric, perhaps because it is highly resolved as the nearest of the bowshocks at a distance of only 140 pc, based on its Hipparcos parallax (Perryman et al. 1997). Most of the nebulae are, to some degree, asymmetric. In some cases, the star appears slightly displaced from the axis of symmetry. Wilkin (2000) discusses such a displacement as the natural result of either a density gradient in the ambient medium transverse to the star's motion or a stellar wind that is anisotropic.

A digital Appendix contains images of all 709 candidate objects from Table 1 in Figures A.1 through A.118 using the same color scheme as Figure 1. These figures depict an angular field of view of 2 arcmin square in most cases to facilitate easy angular size comparison, but for some objects a window of 4′ or 8′ is necessary to include the entire nebula or pertinent features in the immediate environment. For a few objects observed by the SST IRAC but not at MIPS 24 μm, we use the $WISE$ 22 μm image instead. In a just a few instances, the images are constructed using the IRAC 8.0/4.5/3.6 μm images. In some panels a white arrow depicts the proper motion vector magnitude and direction, if proper motion data are available and the measured proper motion is larger than the uncertainties. The vast majority of the 709 candidate bowshock nebulae have small angular sizes and are, consequently, less resolved than the prototypical examples; nevertheless, they share the overall shape, colors, and morphological symmetry of the prototypes.

3.2. *Candidate Bowshock Distribution*

Figure 2 plots the positions of the candidate bowshock nebulae on the Galactic Plane for the 663 objects that lie in the inner two Galactic quadrants at longitudes $-90° < \ell < 90°$. Colors denote the extiction values estimated from the H-4.5 μm color excess: cyan–A_V<2; green–$2 <A_V< 5$; red–$5 <A_V< 10$; magenta–$A_V> 10$; white–no data. The points appear superimposed on a three-color representation of the Galactic Plane with the Infrared Astronomical Satellite ($IRAS$) maps at 25/60/100 μm in blue/green/red, respectively. The distribution of objects is non-uniform, even allowing for the fact that they were selected from surveys covering only a portion of the Plane, principally within one degree of b=0° and within 60° of Galactic Center. For example, there is an overdensity of objects in the vicinity spiral arm tangencies near ℓ=25–30° where the path length through spiral arms is long. The Cygnus-X region near ℓ=79° also exhibits an abundance of objects, probably the result of having multiple nearby (1.2–1.5 kpc) regions of massive star formation. The Carina star forming region near ℓ=287° also exhibits a large number of candidates. A close examination of Figure 2 further reveals that objects having similar extinctions cluster together on the sky, a probable signature of clusterings of massive stars at similar distances and reddennings.

Figure 3 is a histogram of the Galactic latitudes for the 561 candidates that lie within the footprint of the GLIMPSE and MIPSGAL surveys where coverage is complete: $-60° < \ell < 60°, -1° < b < 1°$. The histogram is strongly peaked near b=0°, indicating that very few objects meeting our selection criteria are likely to be found at larger latitudes. The angular scale height for these objects is approximately 0.6° from mid-Plane, identical to the scale height for interstellar bubbles and H II regions (Churchwell et al. 2006).

3.3. *Bowshock Orientations*

Figure 4 displays the positions of bowshocks candidates at $0° < \ell < 60°$ (*upper panel*) and $300° < \ell < 360°$ (*lower panel*). Symbol color and the background three-color IRAS image is the same as in Figure 2. Vector directions indicate the orientation of the bowshock nebulae as determined by the IR morphology. This figure further illustrates that objects with similar extinctions often cluster together on the sky. Furthermore, there are also clusters of objects that have similar orientations. One notable example of this is at the base of the giant gas pillar in M 16 near ℓ=16.8°, b=0.6° where four objects all point toward the source of radiation that has sculpted the pillar.

Figure 5 depicts four candidate bowshock nebulae (G016.8118+00.6679, G016.8760+00.6456, G016.8930+00.6800, and G016.9278+00.6323) in the same field, all pointing in the same direction as the pillars. The central stars of the bowshocks are HD 168183 (O9.5III+B4V), BD-13 4936 (B0e), BD-13 4934 (B1Vp), and BD-13 4937 (B1.5V),

respectively, all early-type stars. BD−13 4937 has a measured proper motion directly *away* from the source of radiation in this young star forming region. These are excellent candidates for "in-situ" bowshocks (Povich et al. 2008) formed by the interaction between the star's own wind and an outflow from the M 16 H II region. In regions like this one, bowshocks exhibit a similar orientation not because they share a common space velocity but because a common source of external momentum flux impinges upon them. There are many other possible "in-situ" bowshocks in our sample, and these are flagged by FH in Table 1.

In order to test the hypothesis that bowshock orientations in this field and others may be correlated on small angular scales, we computed the difference in position angle between each pair of the N=709 nebulae (N×(N−1)/2 unique pairings) and then plotted the mean ΔPA versus angular separation in 8′ bins in Figure 6. For comparison to the null hypothesis (that the position angles are uncorrelated) we randomly shuffled the position angles among the objects 1000 times and computed the mean ΔPA and dispersion in each bin. Figure 6 plots the data (blue points) and the results of the random Monte Carlo iterations, where the heavy black line depicts the mean difference in position angle. The thin solid and dashed lines depict the 1σ and 2σ deviations about the mean. At small angular separations $<20'$ the two blue points lie near the 2σ envelope, while at larger angular separations the points scatter about the mean expected in the case of random orientations. This demonstrates that bowshock positions angles are correlated on small angular scales, as would be expected if some are produced by large-scale external influences such as outflows from nearby H II regions.

We also investigated whether the bowshock nebulae display preferred orientations in the Galactic coordinate system. Figure 7 displays a histogram of the morphological position angles, in Galactic coordinates, for all 709 objects. Error bars designate Poisson uncertainties for each bin. While the overall distribution is generally consistent with random, there is a small excess of objects at $90°$ and $270°$ orientations, parallel to the Plane.

3.4. *Bowshock Sizes*

Figure 8 shows a histogram of the base 10 logarithm of the standoff distance, $\log R_0$, in arcseconds, describing the separation of the central star from the apsis of the arc-shaped nebula. The peak of the distribution in the range 5–$12''$ indicates that the vast majority of the objects are compact, sufficiently small that the angular resolution of *Spitzer Space Telescope* is required to discern the arc-like shape of the nebula. The distribution declines smoothly from $12''$ to about $50''$, beyond which a small number of very large arcs with sizes up to $500''$ populate the distribution more or less uniformly. On the smaller end of the distribution the number of objects drops steeply from sizes of $5''$ to the resolution limit if the IRAC instrument at about $2''$.

Figure 9 plots the angular size of the objects, R_0, versus extinction toward the star, A_V, as inferred from the $H-4.5$ μm color excess, assuming a standard extinction law with $A_V = 9 \times A_K$. A weak correlation is evident, with the largest nebulae being the least extinguished and the smallest nebulae having preferentially larger extinctions. If extinction of the starlight were a proxy for distance, we might expect that the most extinguished objects would also have the smallest angular sizes, but no strong trends are evident.

3.5. *Bowshock Environments*

Figure 10 depicts the fraction of the bowshock candidate sample that lies in apparently isolated environments (I; 70.4%), facing H II regions (FH; 14.5%), facing bright-rimmed clouds (FB; 8.2%), and located within H II regions (H; 6.9%). Many objects designated as FB also lie within H II regions, so FB may entail H; FB and H together make up 15.3% of the sample. Isolated objects (499) make up more than two-thirds of the sample. However, this designation does not necessarily mean that the object is physically isolated from other potential astrophysical influences. In the complex regions near the Galactic Plane, most candidates are seen in projection near dark clouds, star forming regions, and other prominent features. Rather, the isolated designation simply means that the object does not obviously appear to lie within or to directly face a visible H II region, star or bright-rimmed cloud. As such, these are the best candidates for being genuine runaway stars with space velocities sufficient to sweep up ambient material into an infrared-emitting bowshock nebula.

About 14.6% (103 objects) of the sample exhibits a bowshock orientation that faces a prominent H II region within $\simeq 10'$. In such close proximity, outflows from a hot ionized bubble could plausibly interact with the wind of the OB star, producing an "in-situ" type bowshock even if the star does not have a high space velocity. The association of a bowshock nebulae with a particular H II region is necessarily speculative, but the relative orientation occurs frequently enough in our sample that the physical nature of this class of objects is highly suggestive.

Eight percent (58 objects) of the sample faces a bright-rimmed cloud within several arcminutes. Bright-rimmed features represent the photo-excited surfaces of molecular clouds emitting strongly in the 8.0 μm bandpass by virtue

of the solid state features of PAHs. They occur commonly at the peripheries of H II regions where massive stars create cavities or bubbles in the surrounding gas, e.g, the collection of interstellar bubbles cataloged by Churchwell et al. (2006). Figure 11 shows six objects that face bright-rimmed clouds, with the color scheme as in Figure 1. Frequently, this class of objects is located *within* an H II region. Physically, this class of objects may arise when an OB star's wind interacts with a photo-ablated flow from the molecular cloud boundary produced by the UV photons from the same star. The phenomenon may be similar to the stationary shocks visible as ionized arcs at the interface between the wind from θ^1 Ori C and the proplyds in the Orion Nebula (Bally et al. 1998; García-Arredondo et al. 2001). Figure 3 of García-Arredondo et al. (2001) conveniently illustrates the location of one object, proplyd 180-331, that hosts an arc facing the ionization front in the OMC1 molecular cloud rather than the facing the star θ^1 Ori C. Given that the phenomena operating in our subsample of IR-selected bowshock may be similar, we term this subclass of of in-situ bowshock nebulae "photo-evaporative flow" (PEF) bowshocks. However, in Orion, the arcs are very thin features visible primarily in $H\alpha$ and O III, whereas our sample is prominent in the mid-IR dust continuum and the ionization structure is not presently known. One prediction following from this interpretation is that the PEF bowshock candidates, designated here as FB, do not have high space velocities relative to their local environment.

The remaining 7.0% (49 objects) appear to lie within H II regions or interstellar bubbles, as outlined by either bright-rimmed clouds or by pillars of photo-excited gas. While they do not obviously face a bright-rimmed cloud at the periphery of the H II region, they may be produced where a stellar wind interacts with a high-velocity flow of material, including champagne flows. Even so, these objects may overlap with the FB subsample which are frequently found within H II regions.

3.6. *Proper Motions*

Following the analysis of van Buren et al. (1995), we collected proper motion measurements for the stellar counterparts to each bowshock nebula. In this analysis we use proper motion data from the Hipparcos (Perryman et al. 1997), UCAC4 (Zacharias et al. 2013), and the USNO B2 (Monet et al. 2003) catalogs, in order of preference. Of the 709 candidates, only 40% (286) have proper motion data of any kind, and of these only 139 have sufficiently small uncertainties that the proper motion position angles are known to better than 45°. Nevertheless, we computed the measured the angle between the nominal orientation angle of the putative bowshock nebula (column 10 of Table 1) and the proper motion vector. Figure 12 displays a histogram of this distribution in 45° bins between −180° and 180°. Error bars depict the uncertainties, taken to be the square root of the number of objects in each bin. A clear excess in the two bins on either side of zero indicates a preference for proper motions to coincide with the expected direction inferred from the infrared morphology. This suggests that at least 25% of the objects are good candidates for being runaway stars with high space velocities in the direction of apsis of the infrared arc. However, the fraction of sources in this plot having relative position angles exceeding |90°| is large compared to the sample studied by van Buren et al. (1995). Because our sample was selected on the basis of IR morphology rather than on the basis of stars known to have high proper motion (e.g., van Buren et al. 1995; Peri et al. 2015), it is not surprising that our sample displays a broader distribution of relative position angles. The broad distribution of relative position angles may indicate that factors other than a star's peculiar motion could produce relative velocities between a star and the surrounding interstellar material that generate a bowshock nebula. Section 3.5 above discusses physical scenarios that could explain these objects.

4. CONCLUSIONS

We have compiled the largest collection to date of candidate stellar bowshock nebulae selected on the basis of mid-IR morphology at 24 or 22 μm from *Spitzer Space Telescope* and *WISE* sky surveys of the Galactic Plane. The vast majority — 660 of the 709 objects — are identified here for the first time. A minority of objects (∼19%) appear at 8 μm or shorter wavelengths as well, indicating a population of very small hot dust grains within the swept-up nebula, or possibly a PAH contribution. While the infrared images alone do not demonstrate that the tabulated objects are necessarily shocks, the preponderance of ancillary evidence, including proper motions and spectral classifications of the host stars, strongly suggests that this is the best interpretation for the majority of objects. On further investigation, some of the objects may turn out to be other phenomena, such as asymmetric dust shells around evolved stars.

The distribution of these objects on the sky is tightly confined to the Galactic mid-Plane, consistent with their production by massive stars which have strong stellar winds. Proper motions of the central stars, where known, indicate a clear excess of objects having velocity vectors aligned with the symmetry axis of the infrared nebula. This is consistent with their production by a population of massive runaway stars. While the majority of the candidate bowshock nebulae and their central stars lie in relatively isolated environments, a substantial subset (∼20%) either face

giant H II regions or face bright-rimmed clouds. These may, respectively, constitute two classes of "in-situ" bowshocks where either an external flow overruns the star or "photoevaporative flow" bowshocks where a stellar wind interacts with material evaporating from a nearby molecular cloud skin. The correlation of bowshock orientations on angular scales of $\lesssim 10'$ provides evidence that local environmental phenomena, such as outflows from star forming regions, produce the relative motions between a nearby massive star and the ISM that generate the bowshock nebulae.

Table 1 and the Appendix of 709 stellar bowshock candidates may be used to further investigate the origins of runaway stars, phenomena associated with large-scale outflows of gas from star forming regions, and the physics of massive star winds. Additional scrutiny of existing infrared surveys could be expected to find a few additional bowshock candidates, especially at higher Galactic latitudes not covered by our search. However, we expect the yield to be small as the areal density of bowshocks within the *Spitzer Space Telescope* Plane surveys drops rapidly with latitude. In a forthcoming series of papers we will present an analysis of the characteristics of this comprehensive bowshocks sample, including their spectral types, binarity, distances, spectral energy distributions, and local environments.

[a] (van Buren & McCray 1988)

NOTE—The first 20 bowshock nebulae candidates. The complete list of 709 candidates is available as a machine readable table in the electronic version of the Journal. (1) Numeration of this work, 2(Generic name in Galactic coordinates, (3) Right ascension, (4) Declination, (5) First reported discovery reference; T denotes This Work, (6) Alternate name for star, (7) Flag indicating whether source is detected at 8 μm, (8) C denotes that there are multiple candidates for the central star, (9) Angular distance between the star and nebular apex in arcsec, (10) Position angle of nebula in degrees, (11) H-band magnitude, (12) IRAC 4.5 μm or WISE 4.6 μm magnitude, (13) Estimated extinction, (14) Code indicating the local environment, as described in Section 2.2
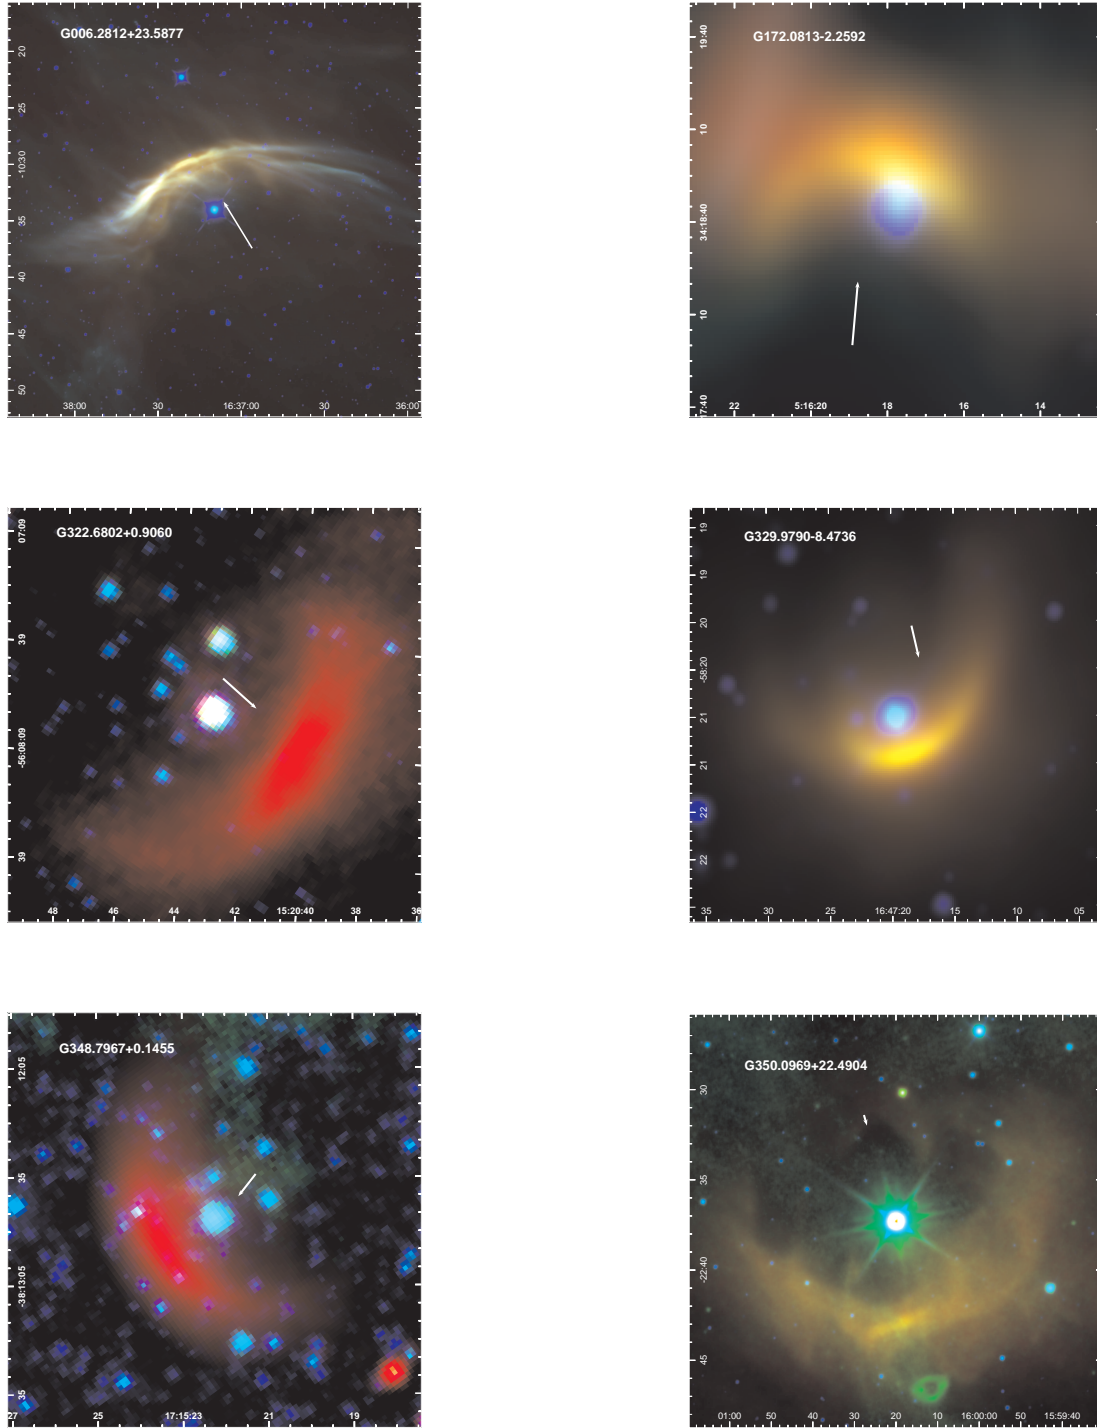

Figure 1. Six prototype bowshock nebulae, with the colors representing either the 24 μm *Spitzer Space Telescope* or 22 μm *WISE* band in red, either the 8 μm *Spitzer Space Telescope* or 12 μm *WISE* image in green, and the 4.5 μm *Spitzer Space Telescope/WISE* image in blue. These six objects are ζ Oph (G006.2812+23.5877; upper left), AE Aur (G172.0813−02.2592; upper right), HD136003 (G322.6802+00.9060; center left), HD150898 (G329.9790−08.4736; center right), HD155755 (G348.7967+00.1455; lower left), HD143275 (G350.0969+22.4904; lower right). Arrows in some panels indicate the direction of proper motion, if known.

(a)
(b)

Figure 2. Candidate bowshock nebula in the inner two Galactic quadrants overlaid on a color representation of the $IRAS$ 25/60/100 μm maps in blue/green/red. Colors denote the extiction values estimated from the $H-4.5$ μm color excess: cyan–$A_{\rm V}<2$; green–2 $<A_{\rm V}<$ 5; red–5 $<A_{\rm V}<$ 10; magenta–$A_{\rm V}>$ 10; white–no data.
Figure 3. Histogram of Galactic latitudes for bowshock candidates within the footprint of the GLIMPSE and MIPSGAL surveys: $-60^{\circ} < \ell < 60^{\circ}, -1^{\circ} < b < 1^{\circ}$.

(a)

(b)

Figure 4. Locations of bowshock candidates drawn as arrows to indicate the morphological orientation of the nebula. Colors designate interstellar extinction values, as in Figure 2. The upper panel shows a portion of the Plane at $0° < \ell < 60°$ while the lower panel shows the $300° < \ell < 360°$ region.
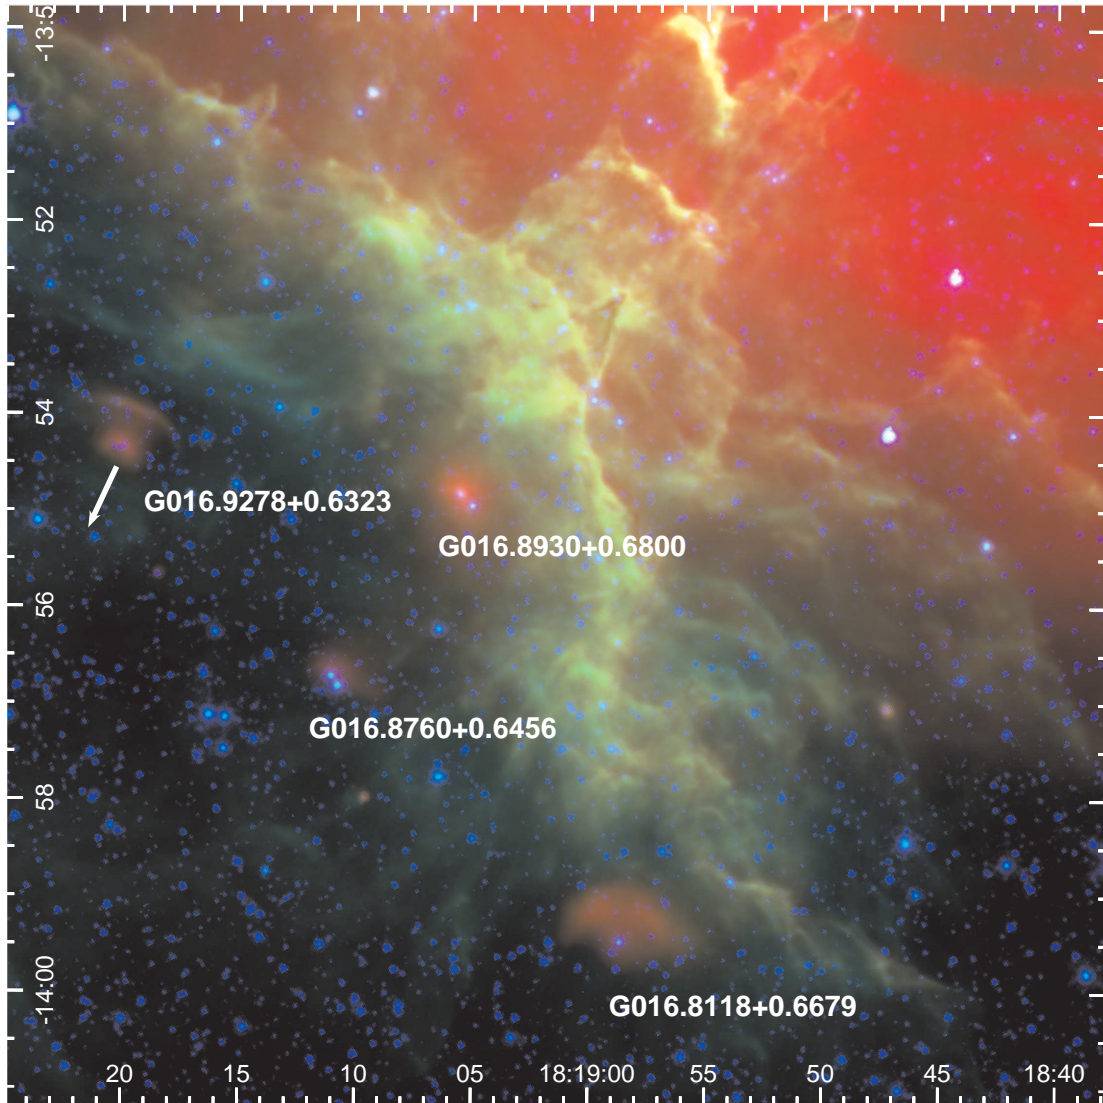

Figure 5. Three color depiction of four candidate bowshock nebulae exhibiting a similar orientation at the base of the giant pillar in M 16. Red/green/blue represent the *Spitzer Space Telescope* 4.5, 8.0, and 24 μm band images. The arrow indicates the proper motion of the one star having measured values.
Figure 6. Mean deviation in bowshock position angle from nearest neighbors as a function of angular separation in arcminutes. Points show the data while the heavy black line shows the mean of 1000 random iterations simulating the null hypothesis that the position angles are uncorrelated. The gray and dashed lines illustrate the 1σ and 2σ deviations from the mean.
Figure 7. Histogram of orientations for candidate bowshock nebulae in Galactic coordinates. Error bars indicate the Poisson uncertainties in each bin.
Figure 8. Histogram of bowshock sizes, as indicated by the standoff distance, R_0, in arcseconds between the central star and apsis of the nebular arc.
Figure 9. Base 10 log of bowshock size versus inferred extinction, A_V.
Figure 10. Fraction of candidates located in apparently isolated environments (I), facing H II regions (FH), facing bright-rimmed clouds (FB), and located within H II regions (H). FB frequently entails H.
Figure 11. Examples of six candidate bowshock nebulae that face an 8 μm bright-rimmed cloud where the shock may be cause by the stellar wind interacting with a photoevaporative flow from the molecular cloud interface. These may be considered a subclass of in-situ bowshocks. The color scheme follows Figure 1.
Figure 12. Difference between the mid-IR morphological axis and proper motion vector of the central star for 139 candidate bowshocks having proper motion position angles with uncertainties less than 45°. The statistically significant excess near zero degrees constitutes evidence that some fraction of these objects are runaway stars having high space velocities in a direction indicated by the IR morphology.

APPENDIX

A. ATLAS OF IMAGES

This electronic-only appendix contains an atlas of three-color images for each of the 709 bowshock nebula candidates. For the majority of the candidates that have *Spitzer Space Telescope* data, the color scheme is 24/8.0/4.5 μm in red/green/blue. For objects outside the coverage of the *Spitzer Space Telescope* surveys, we use the *WISE* 22/12/4.6 bands in red/green/blue. In a few cases where the *Spitzer Space Telescope* 24 μm data are not available, we substitute the *WISE* 22 μm data. Images are $2'$ square unless a larger field of view is required to show the entire nebulae or pertinent surrounding features. White arrows on some images depict the direction and magnitude of central star's proper motion, where known.
